ABSTRACT
In this paper, we propose a new mutual information (MMI) framework for multi-agent reinforcement learning (MARL) to enable multiple agents to learn coordinated behaviors by regularizing the accumulated return with the simultaneous mutual information between multi-agent actions. By introducing a latent variable to induce nonzero mutual information between multi-agent actions and applying a variational bound, we derive a tractable lower bound on the considered MMI-regularized objective function. The derived tractable objective can be interpreted as maximum entropy reinforcement learning combined with uncertainty reduction of other agents’ actions. Applying policy iteration to maximize the derived lower bound, we propose a practical algorithm named variational maximum mutual information multi-agent actor-critic (VM3-AC), which follows centralized learning with decentralized execution (CTDE). We evaluated VM3-AC for several games requiring coordination, and numerical results show that VM3-AC outperforms other MARL algorithms in multi-agent tasks requiring high-quality coordination.

1 INTRODUCTION
With the success of RL in the single-agent domain [13, 18], MARL is being actively studied and applied to real-world problems such as traffic control systems and connected self-driving cars, which can be modeled as multi-agent systems requiring coordinated control [1, 12]. The simplest approach to MARL is independent learning, which trains each agent independently while treating other agents as a part of the environment, but this approach suffers from the problem of non-stationarity of the environment. A common solution to this problem is to use fully-centralized critic in the framework of centralized training with decentralized execution (CTDE) [8, 11, 16, 20, 21]. For example, MADDPG [16] uses a centralized critic to train a decentralized policy for each agent, and COMA [4] uses a common centralized critic to train all decentralized policies. However, these approaches assume that decentralized policies are independent and hence the joint policy is the product of each agent’s policy. Such non-correlated factorization of the joint policy limits the agents to learn coordinated behavior due to negligence of the influence of other agents [3, 26]. Recently, mutual information (MI) between multiple agents’ actions has been considered as an effective intrinsic reward to promote coordination in MARL [10]. In [10], MI between agents’ actions is captured as social influence and the goal is to maximize the sum of accumulated return and social influence between agents’ actions. It is shown that the social influence approach is effective for sequential social dilemma games. In this framework, however, causality between actions under coordination is required, and it is not straightforward to coordinate multi-agents’ simultaneous actions. In certain multi-agent games, coordination of simultaneous actions of multiple agents is required to achieve cooperation for a common goal. For example, suppose that a pack of wolves tries to catch a prey. To catch the prey, coordinating simultaneous actions among the wolves is more effective than coordinating one wolf’s action and other wolves’ actions at the next time because the latter case causes delay in coordination. In this paper, we propose a new approach to the MI-based coordination for MARL to coordinate simultaneous actions among multiple agents under the assumption of the knowledge of timing information among agents. Our approach is based on introducing a common latent variable to induce MI among simultaneous actions of multiple agents and on a variational lower bound on MI that enables tractable optimization. Under the proposed formulation, applying policy iteration by redefining value functions, we propose the VM3-AC algorithm for MARL to learn coordination of simultaneous actions among multiple agents. Numerical results show its superior performance on cooperative multi-agent tasks requiring coordination.

2 RELATED WORK
MI is a measure of dependence between two variables [2] and has been considered as an effective intrinsic reward for MARL [10, 24].
proposed an intrinsic reward for empowerment by maximizing MI between agent’s action and its future state. [24] proposed two intrinsic rewards capturing the influence based on a decision-theoretic measure and MI between an agent’s current actions/states and other agents’ next states. In particular, [10] proposed a social influence intrinsic reward, which basically captures the mutual information between multiple agents’ actions to achieve coordination, and showed that the social influence formulation yields good performance in sequential social dilemma environments. The difference of our approach from the social influence to MI-based coordination will be explained in Section 3 and Section 4.1.

Some previous works approached correlated policies from different perspectives. [15] proposed explicit modeling of correlated policies for multi-agent imitation learning, and [26] proposed a recursive reasoning framework for MARL to maximize the expected return by decomposing the joint policy into own policy and opponents’ policies. Going beyond adopting correlated policies, our approach maximizes the MI between multiple agents’ actions which is a measure of correlation.

In our approach, the MI between agents’ action distributions is decomposed as the sum of each agent’s action entropy and a variational term related to prediction of other agents’ actions. Hence, our framework can be interpreted as enhancing correlated exploration by increasing the entropy of own policy [7] while decreasing the uncertainty about other agents’ actions. Some previous works proposed other techniques to enhance correlated exploration [17, 28]. MAVEN addressed the poor exploration problem of QMIX by proposing other techniques to enhance correlated exploration [17, 28].

MAVEN framework can be interpreted as enhancing correlated exploration by an RMI between agents’ actions. Hence, our MI-based objective function for joint policy $\pi$ is given by

$$f(\pi) = \mathbb{E}_{\tau \sim \pi} \left[ \sum_{t=0}^{\infty} y^t (r_t + \alpha \sum_{(i,j)|i \neq j} I(a_i^t; a_j^t|s_t)) \right],$$

where $I(a_i^t; a_j^t|s_t)$ is the MI between $a_i^t \sim \pi_i(\cdot|s_t)$ and $a_j^t \sim \pi_j(\cdot|s_t)$, and $\alpha$ is the temperature parameter that controls the relative importance of the MI against the reward. It is known that by regularization with MI in the objective function (1), the policy of each agent is encouraged to coordinate with other agents’ policies. There are several approaches to implement (1). Under the social influence framework in [10], the MI is decomposed as

$$I(a_i^t; a_j^t|s_t) = \sum_{a_i^t} \sum_{a_j^t} p(a_i^t, a_j^t|s_t) \log \frac{p(a_i^t, a_j^t|s_t)}{p(a_i^t|s_t)p(a_j^t|s_t)}$$

$$= \sum_{a_i^t} \sum_{a_j^t} \int p(a_i^t|s_t) \int p(a_j^t|s_t) \log \frac{p(a_i^t, a_j^t|s_t)}{p(a_i^t|s_t)p(a_j^t|s_t)}$$

$$= \sum_{a_i^t} \int p(a_i^t|s_t) D_{KL}(p(a_j^t|a_i^t, s_t)||p(a_j^t|s_t)),$$

$$\triangleq \text{social influence of agent } i \text{ on agent } j$$

where $D_{KL}(\cdot||\cdot)$ is the Kullback-Leibler divergence. In this decomposition, influencing Agent $i$’s policy is given by $\pi^i = p(a_j^t|s_t)$ and influenced Agent $j$’s policy is given by $\pi^j = p(a_i^t|a_j^t, s_t)$. The social influence is defined as the difference between $p(a_j^t|s_t)$ and $p(a_j^t|s_t)$. Hence, at time step $t$, influencing Agent $i$ acts first and then influenced Agent $j$ acts based on $a_j^t$ after Agent $i$ acts, as shown in Fig. 1(a). This sequential dependence between actions prevents multiple agents from performing simultaneous actions, which is an assumption of most decentralized execution. In addition, the social influence approach needs a strategy for action ordering because it divides all agents into a set of influencers and a set of influencees. One way to remove this action ordering is to model other agents [10]. In this case, the causal influence of action $a_i^t$ of Agent $i$ at time $t$ on action $a_j^{t+1}$ of Agent $j$ at time $t + 1$ is considered, as shown in Fig. 1(b), i.e., the social influence $D_{KL}(p(a_j^{t+1}|a_i^t, s_t)||p(a_j^{t+1}|s_t))$ instead of the influence term in (4).
is considered based on modeling \( p(\hat{a}_t | a_t, s_t) \) so that actions \( a_t^i \) and \( a_t^j \) can be performed simultaneously without ordering. In this case, however, the actually considered MI is \( I(\hat{a}_t^i; \hat{a}_t^j | s_t) \) and is not the MI between \( a_t^i \) and \( a_t^j \) occurring at the same time. In this paper, we propose a different approach to MI regularization which enables simultaneous coordination between actions \( a_t^i \) and \( a_t^j \) both at time \( t \) without action ordering.

4 THE PROPOSED APPROACH

We assume that the environment is fully observable, i.e., each agent can observe the environment state \( s_t \) for theoretical development in this section, and will consider partially observable environment for practical algorithm construction under CTDE in the next section.

4.1 Formulation

Without explicit dependency between actions, \( \pi^t(\cdot | s_t) \) and \( \pi^j(\cdot | s_t) \) are conditionally independent for given environment state \( s_t \) and consequently the mutual information is always zero, i.e., \( I(\pi^i(\cdot | s_t); \pi^j(\cdot | s_t)) = 0 \). Then, the MI-regularized objective function (1) reduces to the standard MARL objective of only the accumulated return. In order to circumvent this difficulty, we propose a novel method to induce MI between actions. Our approach for inducing MI between concurrent two actions \( a_t^i \) and \( a_t^j \) of Agents \( i \) and \( j \) at time \( t \) is to introduce a latent variable \( Z_t \), as shown in Fig. 1(c). We assume that the latent variable \( Z_t \) has a prior distribution \( p(Z_t) \) and that actions \( a_t^i \) and \( a_t^j \) are generated from the state variable \( s_t \) and the latent random variable \( Z_t \). Thus, Agent \( i \)'s action \( a_t^i \) at time \( t \) is drawn from the policy distribution of Agent \( i \) as

\[
a_t^i \sim \pi^i(\cdot | s_t, Z_t), \quad i = 1, 2, \ldots, N, \tag{5}
\]

where we use the upper case for random variables and the lower case for their realizations in the conditioning input terms for notational clarification. Then, even in case of deterministic policy, there is randomness in \( a_t^i \) for given \( s_t = s_t \) due to the random input \( Z_t \) since a function of random variable is a random variable. In case of stochastic policy, there is additional randomness in \( a_t^i \) for given \( s_t = s_t \) due to stochasticity of the policy itself. One can view the randomness due to \( Z_t \) as a perturbation to nominal \( a_t^i \) for given \( s_t = s_t \). With the common perturbation-inducing variable \( Z_t \) to all agents’ policies, two random variables \( a_t^i \) and \( a_t^j \) conditioned on \( s_t = s_t \) are correlated due to common \( Z_t \), and then nonzero MI \( I(\hat{a}_t^i; \hat{a}_t^j | s_t) \) between concurrent \( a_t^i \) and \( a_t^j \) is induced. We aim to exploit this correlation for action coordination and correlated exploration in the training phase. (See Appendix A for a simple example and explanation of our basic idea with the simple example.)

With nontrivial MI \( I(\hat{a}_t^i; \hat{a}_t^j | s_t) \), we now express this MI. First, note in (4) that we need \( p(\hat{a}_t^i | a_t^i, s_t) \) to compute the MI but we do not want to use \( p(\hat{a}_t^i | a_t^i, s_t) \) directly because \( p(\hat{a}_t^i | a_t^i, s_t) \) requires Agent \( j \) to know the action \( a_t^j \) of Agent \( i \). For this, we adopt a variational distribution \( q(\hat{a}_t^i | a_t^i, s_t) \) to estimate \( p(\hat{a}_t^i | a_t^i, s_t) \) and derive a lower bound on the MI \( I(\hat{a}_t^i; \hat{a}_t^j | s_t) \) as follows:

\[
I(\hat{a}_t^i; \hat{a}_t^j | s_t) = \int q(\hat{a}_t^i | a_t^j, s_t) \log \frac{p(\hat{a}_t^i, \hat{a}_t^j | s_t)}{p(\hat{a}_t^i | s_t)p(\hat{a}_t^j | s_t)} \, \text{d}Q(\hat{a}_t^i, \hat{a}_t^j) = \int q(\hat{a}_t^i | a_t^j, s_t) \log \frac{p(\hat{a}_t^i | a_t^j, s_t)}{p(\hat{a}_t^i | s_t)p(\hat{a}_t^j | s_t)} \, \text{d}Q(\hat{a}_t^i, \hat{a}_t^j) \\
= \mathbb{E}_{p(\hat{a}_t^i, \hat{a}_t^j | s_t)} \left[ \log \frac{q(\hat{a}_t^i | a_t^j, s_t)}{p(\hat{a}_t^i | s_t)} \right] \\
\quad \times \mathbb{E}_{p(a_t^j | s_t)} \left[ KL(p(a_t^j | s_t) || q(a_t^j | a_t^j, s_t)) \right] \\
\geq H(a_t^i | s_t) + \mathbb{E}_{p(a_t^j | s_t)} \left[ \log q(a_t^i | a_t^j, s_t) \right], \tag{6}
\]

where the last inequality in (6) holds because the KL divergence is always non-negative. Note that \( H(a_t^i | s_t) \) is the entropy of \( a_t^i \) given \( s_t \), i.e., the entropy of the following marginal distribution of \( a_t^i \) in our case:

\[
\hat{\pi}^i(\cdot | s_t) := \int q(\hat{a}_t^i | s_t = s_t, Z = z_t) \, p(Z_t) \, dz_t. \tag{7}
\]

For the variational distribution \( q(a_t^i | a_t^j, s_t) \) we consider a class of distributions \( Q \), i.e., \( q(a_t^i | a_t^j, s_t) \in Q \). The lower bound (6) becomes tight when \( q(a_t^i | a_t^j, s_t) \approx p(a_t^i | a_t^j, s_t) \) well, i.e., \( D_{KL}(p(a_t^i | a_t^j, s_t) || q(a_t^i | a_t^j, s_t)) \) is small. Note that in our expansion, the lower bound on the MI \( I(\hat{a}_t^i; \hat{a}_t^j | s_t) \) is expressed as the sum of the action entropy \( H(a_t^i | s_t) \) and the negative of the cross entropy of \( q(a_t^i | a_t^j, s_t) \) relative to \( p(a_t^i | a_t^j, s_t) \) averaged over \( p(a_t^j | s_t) \). Using the symmetry of MI, we can rewrite the lower bound as

\[
I(\hat{a}_t^i; \hat{a}_t^j | s_t) \geq \frac{1}{2} \left[ H(a_t^i | s_t) + H(a_t^j | s_t) \right] + \mathbb{E}_{p(a_t^j | s_t)} \left[ \log q(a_t^i | a_t^j, s_t) + \log q(a_t^j | a_t^j, s_t) \right]. \tag{8}
\]

Then, our goal is to maximize this lower bound of MI by using a tractable approximation \( q(a_t^i | a_t^j, s_t) \in Q \). Our decomposition of MI based on the action entropy and the cross entropy is effective in our variational formulation for MI-based MARL. Consider one of the cross entropy terms in the right-hand side (RHS) of (8):

\[
\mathbb{E}_{p(a_t^i | a_t^j, s_t)} \left[ \log q(a_t^i | a_t^j, s_t) \right],
\]

which can be rewritten as

\[
\mathbb{E}_{p(a_t^i | a_t^j, s_t)} \left[ \log q(a_t^i | a_t^j, s_t) \right] = -\mathbb{E}_{p(a_t^i | s_t)} \left[ H(p(a_t^i | a_t^j, s_t)) \right] \\
\quad + D_{KL}(p(a_t^i | a_t^j, s_t) || q(a_t^i | a_t^j, s_t)). \tag{9}
\]

based on the well-known decomposition of the cross entropy. Hence, by maximizing this cross entropy term, due to the negation in (9) we can learn \( \pi^i \) (generating \( a_t^i \)) and \( \pi^j \) (generating \( a_t^j \)) so that the conditional entropy \( H(p(a_t^i | a_t^j, s_t)) \) of \( a_t^j \) given \( a_t^i \) is minimized, i.e., the two actions are more correlated to each other, and learn \( q \) that closely approximates the true \( p(a_t^i | a_t^j, s_t) \), i.e., the \( D_{KL} \) term in (9) is minimized.

4.2 Modified Policy Iteration

Our algorithm construction is based on policy iteration. In order to develop policy iteration for the proposed MI framework, we
first replace the original MI-regularized objective function (1) with the following tractable objective function based on the variational lower bound (8):

\[
J(\pi, q) = \mathbb{E}_{z_t \sim P_z} \left[ \sum_{i=1}^{\infty} y^i (r_i(s_i, a_i) + \alpha N \sum_{i=1}^{N} \log q(a_i'| s_i, z_t)) \right],
\]

where \( \pi = [\pi^1, \ldots, \pi^N] \) and \( \pi^i \) is given by (5) and \( a_i = [a^i_1, \ldots, a^i_N] \).

Then, we determine the individual objective function \( J^i(\pi^i, q) \) for Agent \( i \) as the sum of the terms in (10) associated with Agent \( i \)'s policy \( \pi^i \) or action \( a^i \), given by

\[
J^i(\pi^i, q) = \mathbb{E}_{z_t \sim P_z} \left[ \sum_{i=1}^{\infty} y^i (r_i(s_i, a_i) + \beta \cdot H(a_i'| s_t)) \right] + \frac{\beta}{N} \sum_{j \neq i} \log q(a_j'| s_i, \pi^i) + \log q(a_i'| s_i, \pi^i),
\]

where \( \beta = \alpha N \) is the temperature parameter. Note that maximizing the term (a) in (11) implies that each agent maximizes the weighted sum of the return and the action entropy, which can be interpreted as an extension of maximum entropy RL [7] to multi-agent setting. On the other hand, maximizing the term (b) with respect to \( \pi^i \) and \( q \) means that we update the policy \( \pi^i \) so that the conditional entropy of \( a^i_j \) given \( a^i_{\cdot} \) and the conditional entropy of \( a^i_j \) given \( a^i_{\cdot} \) are reduced, as already mentioned below (9). Thus, the objective function (11) can be interpreted as the \textit{maximum entropy MARL objective combined with action correlation or coordination}. Hence, the proposed objective function (11) can be considered as one implementation of the concept of \textit{correlated exploration} in MARL [17].

Now, in order to learn policy \( \pi^i \) to maximize the objective function (11), we modify the policy iteration in standard RL. For this, we redefine the value functions for Agent \( i \) as

\[
Q^i_\pi(s, a) \triangleq \mathbb{E}_{z_t \sim P_z} \left[ r(s_t, a_t) + \gamma \mathbb{E}_{x' \sim P_x} \left[ V^\pi_i(s') \right] \right],
\]

\[
V^\pi_i(s) \triangleq \mathbb{E}_{z_t \sim P_z} \left[ \sum_{t=0}^{\infty} y^t (r_t + \beta \cdot H(a_t'| s_t)) \right] + \frac{\beta}{N} \sum_{j \neq i} \log q(a_j'| s_i, \pi^i) + \log q(a_i'| s_i, \pi^i),
\]

where \( q^{(i,j)}(a^i_j, a^i_{\cdot}| s_t) \) \( \triangleq q(a^i_j| a^i_{\cdot}, s_t) q(a^i_{\cdot}| a^i_j, s_t) \). Then, the Bellman operator corresponding to \( V^\pi_i \) and \( Q^\pi_i \) on the value function estimates \( V_i(s) \) and \( Q_i(s, a) \) is given by

\[
\mathcal{T}^\pi Q_i(s, a) = r(s, a) + \gamma \mathbb{E}_{x' \sim P_x} [V_i(s')],
\]

where \( V_i(s) = \left[ Q_i(s, a) - \beta \log \pi^i(a^i| s_t) + \frac{\beta}{N} \sum_{j \neq i} \log q^{(i,j)}(a^i_j, a^i_{\cdot}| s_t) \right], \) and \( \pi^i \) is the marginal distribution given in (7). In the policy evaluation step, we compute the value functions (12) and (13) by applying the modified Bellman operator \( \mathcal{T}^\pi \) repeatedly to an initial function \( Q^{(0)}_i \).

\textbf{Proposition 1. (Variational Policy Evaluation).} For fixed \( \pi \) and the variational distribution \( q \), consider the modified Bellman operator \( \mathcal{T}^\pi \) in (14) and an arbitrary initial function \( Q^{(0)}_i : S \times \mathcal{A} \rightarrow \mathbb{R} \), and define \( \tilde{Q}^{(k+1)}_i = \mathcal{T}^\pi Q^{(k)}_i \). Then, \( \tilde{Q}^{(k)}_i \) converges to \( Q^\pi_i \) defined in (12).

\textbf{Proof.} See Appendix B.

In the policy improvement step, we update the policy and the variational distribution by using the value function evaluated in the policy evaluation step. Here, each agent updates its policy and variational distribution while keeping other agents’ policies fixed as follows: \( \pi^i_{k+1}, q_{k+1} \triangleq \arg \max_{\pi^i, q} \mathbb{E}_{z_t \sim P_z} (Q_i(s, a) - \beta \log \pi^i(a^i| s_t) + \frac{\beta}{N} \sum_{j \neq i} \log q^{(i,j)}(a^i_j, a^i_{\cdot}| s_t)).
\]

\textbf{Proposition 2. (Variational Policy Improvement).} Let \( \pi^i_{k+1} \) and \( q_{k+1} \) be the updated policy and the variational distribution from (15).

Then, \( Q^{\pi_{k+1}} Q^{\pi_{k+1}}_{\pi^{i^*}_{k+1}}(s, a) \geq Q^{\pi_{k+1}} Q^{\pi_{k+1}}_{\pi^{i^*}_{k}}(s, a) \) for all \( (s, a) \in (S \times \mathcal{A}) \). Here, \( Q^{\pi_{k+1}} Q^{\pi_{k+1}}_{\pi^{i^*}_{k+1}}(s, a) \) means \( Q^{\pi_{k+1}}(s, a)|_{\pi = \pi^{i^*}_{k+1}}. \)

\textbf{Proof.} See Appendix B.

The modified policy iteration is defined as applying the variational policy evaluation and variational improvement steps in an alternating manner. Each agent trains its policy, critic and the variational distribution to maximize its objective function (11).

\section{Algorithm Construction}

Summarizing the development above, we now propose the variational maximum mutual information multi-agent actor-critic (VM3-AC) algorithm, which can be applied to continuous and partially observable multi-agent environments under CTDE. The overall operation of VM3-AC is shown in Fig. 2. Under CTDE, each agent’s policy is conditioned on local observation, and centralized critics are conditioned on either the environment state or the observations of all agents, depending on the situation [16]. Let \( x \) denote either the environment state \( s \) or the observations of all agents \( (o_1, \ldots, o_N) \), whichever is used. In order to deal with the large continuous state-action spaces, we adopt deep neural networks to approximate the required functions. For Agent \( i \), we parameterize the policy as \( \pi^i_{\phi^i}(a^i| x, z) \) with parameter \( \phi^i \), the variational distribution as \( q^{\pi_{\phi^i}}(a^i_j| x, (o^i_1, \ldots, o^i_j)) \) with parameter \( \phi^2 \), the state-value function as \( V^{\pi_{\phi^2}}(x) \) with parameter \( \phi^3 \), and two action-value functions as \( Q^{\pi_{\phi^1}}(x, a) \) and \( Q^{\pi_{\phi^1}}(x, a) \) with parameters \( \theta^{1,1} \) and \( \theta^{1,2} \). Note that in the original variational distribution, \( a^i \) is conditioned on \( a_{i-1} \) and \( s_i \). In the partially observable case, we replace \( s_i \) with \( (o_i, a_i) \).
Hence, there exists Jensen’s inequality type approximation error. Consider the two action-value functions to prevent the overestimation problem. In other words, we require all agents to have the same Gaussian random sequence generator only once in the beginning of the execution phase. In order to make all agents have the same Gaussian random sequence generator, we require all agents to have the same realization of latent variables. For simplicity of computation, we took the expectation $E$ in the beginning of the episode. Second, we exploit the property of the exponential moving average method. We implement the reparameterization trick to estimate the stochastic gradient of policy loss. Then, the action of agent $i$ is given by $a^i = f_{\phi^i}(s^i; e^i, z)$, where $e^i \sim N(0, I)$ and $z \sim N(0, I)$. The policy for Agent $i$ and the variational distribution are trained to minimize the following policy improvement loss, $L_{\pi_i \theta_i}(\phi^i, \xi)$.

The value functions $V^i_t(x)$, $Q^i_t(x, a)$ are updated based on the modified Bellman operator defined in (13) and (14). The state-value function $V^i_t(x)$ is trained to minimize the following loss function:

$$L_V(\psi^i) = E_{s_t \sim D} \left[ \frac{1}{2} (V^i_t(x_t) - \hat{V}^i_t(x_t))^2 \right]$$

where $D$ is the replay buffer that stores the transitions $(x_t, a_t, r_t, x_{t+1})$; $Q^i_{\min}(x_t, a^i_t) = \min[Q^i_{\phi^i}(x_t, a^i_t), Q^i_{\phi^2}(x_t, a^i_t)]$ is the minimum of the two action-value functions to prevent the overestimation problem [5]; and

$$\hat{V}^i_t(x_t) = E_{z_t \sim N(0, I), (a^i_t, o^i_t)} Q^i_{\min}(x_t, a^i_t) + \beta \log \pi^i_{\phi^i}(a^i_t | o^i_t, z_t)$$

Note that in the second term of the RHS of (17), originally we should have used the marginalized version, $-\beta \log \pi^i_{\phi^i}(a^i_t | o^i_t, z_t) = -\beta \log E_{z_t \sim N(0, I)} [\pi^i_{\phi^i}(a^i_t | o^i_t, z_t)].$ However, for simplicity of computation, we took the expectation $E_{z_t \sim N(0, I)}$ outside the logarithm. Hence, there exists Jensen’s inequality type approximation error. We observe that this approximation works well.

The two action-value functions are updated by minimizing the loss

$$L_Q(\theta^i) = E_{(x_t, a_t) \sim D} \left[ \frac{1}{2} (Q^i_{\theta^i}(x_t, a_t) - \hat{Q}(x_t, a_t))^2 \right]$$

where

$$\hat{Q}(x_t, a_t) = r_t(x_t, a_t) + \gamma \hat{E}_{x_{t+1}}[V^i_{\theta^i}(x_{t+1})]$$

and $V^i_{\theta^i}$ is the target value network, which is updated by the exponential moving average method. We implement the reparameterization trick to estimate the stochastic gradient of policy loss. We use $Q^i_{\phi^i}(x_t, a_t)$ and $V^i_{\theta^i}(x_t)$ in the following policy improvement loss, $L_{\pi_i \theta_i}(\phi^i, \xi)$:

$$= E_{s_t \sim D, \ e^i \sim N(0, I), z \sim N(0, I)} \left[ -Q^i_{\phi^i}(x_t, a_t) + \beta \log \pi^i_{\phi^i}(a^i_t | o^i_t, z) \right]$$

where

$$q^{(i,j)}_{\phi^i} = q^{(i,j)}_{\phi^i}(a^i_t | o^i_t, z) \pi^j_{\phi^j}(a^j_t | o^j_t, o^j_t) \pi^i_{\phi^i}(a^i_t | o^i_t, z)$$

Note that in the second term of the RHS of (17), originally we should have used the marginalized version, $-\beta \log \pi^i_{\phi^i}(a^i_t | o^i_t, z_t) = -\beta \log E_{z_t \sim N(0, I)} [\pi^i_{\phi^i}(a^i_t | o^i_t, z_t)].$ However, for simplicity of computation, we took the expectation $E_{z_t \sim N(0, I)}$ outside the logarithm. Hence, there exists Jensen’s inequality type approximation error. We observe that this approximation works well.
zero-mean Gaussian input variable $z_t$ to the policy network. During the centralized training period, the parameters $\phi^1, \ldots, \phi^N$ of the policy networks $\pi^i_\phi(a \mid o^i, z)$, $\pi^N_\psi(a \mid o^N, z)$ (with input $(o^i, z)$ and output $a$) are learned so that actions $a^1, \ldots, a^N$ are coordinated for random perturbation input $z_t$ drawn from $P_Z$. Note that the coordination behavior is learned and engraved into the parameters $\phi_1, \ldots, \phi_N$ not into the input $z_t$. So, we only use this stored parameter information during the decentralized execution phase. We apply the common mean value $E(z_t)$ to the $z_t$ input of the trained policy network $\pi^i_\psi(a^i \mid o^i, z_t)$ of Agent $i$, $\forall i$. In this case, actions $a^1, \ldots, a^N$ are independent conditioned on $o_t \equiv (o^1, \ldots, o^N)$ but a specific joint bias (most representative joint bias) is applied to actions $a^1, \ldots, a^N$. We expect that this joint bias is helpful and this situation is described in a toy example in Appendix A. In this way, the proposed algorithm is fully operative under CTDE. The ablation study is provided in Sec. 6.

6 EXPERIMENT

In this section, we provide numerical results on both continuous and discrete action tasks.

Experiment on continuous action tasks We consider the following continuous action tasks with the varying number of agents: multi-walker [6], predator-prey [16], cooperative treasure collection [9], and cooperative navigation [16]. The detailed setting of each task is provided in Appendix F. Here, we considered four baselines: 1) MADDPG [16] - an extension of DDPG with a centralized critic to train a decentralized policy for each agent. 2) Multi-agent actor-critic (MA-AC) - a variant of VM3-AC ($\beta = 0$) without the latent variable. 3) Multi-agent variational exploration (MAVEN) [17]. Similarly to VM3-AC, MAVEN introduced latent variable and variational approach for optimizing the mutual information. However, MAVEN does not consider the mutual information between actions but considers the mutual information between the latent variable and trajectories of the agents. 4) Social Influence with MOA (SI-MOA) [10], which is explained in Section 3. Both MAVEN and SI-MOA are implemented on top of MA-AC since we consider continuous action-space environments.

Fig. 3 shows the learning curves for the considered four environments with the different numbers of agents. The y-axis denotes the average of all agents’ rewards averaged over 7 random seeds, and the x-axis denotes the time step. The hyperparameters including the temperature parameter $\beta$ and the dimension of the latent variable are provided in Appendix E. As shown in Fig. 3, VM3-AC outperforms the baselines in the considered environments. Especially, in the case of the multi-walker environment, VM3-AC has a large performance gain over existing state-of-the-art algorithms. This is because the agents in the multi-walker environment are strongly required to learn simultaneous coordination in order to obtain high rewards. In addition, the agents in the predator-prey environment, where the number of agents is four, should spread out in groups of two to get more rewards. In this environment, VM3-AC also has a large performance gain. Thus, it is seen that the proposed MMI framework improves performance in complex multi-agent tasks requiring high-quality coordination. It is observed that both MAVEN and SI-MOA outperform the basic algorithm MA-AC but not VM3-AC. Hence, the numerical results show that the way of using MI by the proposed VM3-AC algorithm has some advantages over those by MAVEN and SI-MOA, especially for MARL tasks requiring coordination of concurrent actions.

6.1 Ablation Study and Discussion

In this subsection, we provide ablation studies and discussion on the major techniques and hyperparameters of VM3-AC: 1) mutual information versus entropy 2) the latent variable, 3) the temperature parameter $\beta$, 4) injecting zero vector instead of the latent variable $z$ to policies in the execution phase and 5) scalability.
Figure 3: Performance of MADDPG (blue), MA-AC (green), MAVEN (purple), SI-MOA (black), and VM3-AC (the proposed method, red) on multi-walker environments (a)-(b), predator-prey (c)-(e), cooperative treasure collection (f)-(g), and cooperative navigation (h). (MW, PP, CTC, and CN denote multi-walker, predator-prey, cooperative treasure collection and cooperative navigation, respectively)

Figure 4: Performance of DOP (green), FOP (blue), LICA (black), MAVEN (purple), VDAC (orange) and VM3-AC (red) on three maps in the modified SMAC environment.

**Mutual information versus entropy:** The proposed MI framework maximizes the sum of the action entropy and the negative of the cross entropy of the variational conditional distribution relative to the true conditional distribution, which provides a lower bound of MI between actions. As aforementioned, maximizing the sum of the action entropy and the negative of the cross entropy of the variational conditional distribution relative to the true conditional distribution enhances exploration and predictability for other agents’ actions. Hence, the proposed MI framework enhances correlated exploration among agents.

We compared VM3-AC with multi-agent-SAC (MA-SAC), which is an extension of maximum entropy soft actor-critic (SAC) [7] to multi-agent setting. For MA-SAC, we extended SAC to multi-agent settings in the manner of independent learning. Each agent trains its decentralized policy using decentralized critic to maximize the weighted sum of the cumulative return and the entropy of its policy. Adopting the framework of CTDE, we replaced decentralized critic with centralized critic which incorporates observations and actions of all agents.

We performed an experiment in the predator-prey environment with four agents where the number of required agents to catch the prey is two. In this environment, the agents started at the center of the map. Hence, the agents should spread out in the group of two to catch preys efficiently. Fig.6 shows the positions of the four agents at five time-steps after the episode starts. The first and second rows in Fig.6 show the results of VM3-AC and MA-SAC in the early stage of the training, respectively. It is seen that the agents of VM3-AC explore in the group of two while the agents of MA-SAC tend to explore independently. We provided the performance comparisons of VM3-AC with MA-SAC in Fig.5 (a) and (b).

**Latent variable:** The role of the latent variable is to induce MI among concurrent actions and inject an additional degree of freedom for action control. We compared VM3-AC and VM3-AC without the latent variable (implemented by setting dimension \( z = 0 \)) in the multi-walker environment. In both cases, VM3-AC yields
We used deterministic evaluation based on 20 episodes generated with respect to the temperature parameter without noticeable performance loss. Please see Appendix A for the return over 7 seeds, and the result is shown in Table 1. It is seen that the mean vector replacement method yields almost the same performance and enables fully decentralized execution so as to execute actions without communication during the execution phase. As mentioned in Section 5, we applied the mean vector of \( z_t \), i.e., \( \mathbb{E}(z_t) \) to the \( z_t \)-input of the policy deep neural network \( \pi^i_{\phi^i}(\cdot|o_t^i, z_t) \) during the execution phase so as to execute actions without communication in the execution phase. We compared the performance of decentralized policies that use the mean vector \( \mathbb{E}(z_t) \) and decentralized policies which use the latent variable \( z_t \) assuming communication. We used deterministic evaluation based on 20 episodes generated by the corresponding deterministic policy, i.e., each agent selects action using the mean network of Gaussian policy \( \pi^i_{\phi^i} \). We averaged the return over 7 seeds, and the result is shown in Table 1. It is seen that the mean vector replacement method yields almost the same performance and enables fully decentralized execution without noticeable performance loss. Please see Appendix A for intuition.

**Temperature parameter \( \beta \):** The role of temperature parameter \( \beta \) is to control the relative importance between the reward and the MI. We evaluated VM3-AC by varying \( \beta = [0, 0.05, 0.1, 0.15] \) in the multi-walker environment with \( N = 3 \) and \( N = 4 \). Fig. 5(c) and 5(d) show that VM3-AC with the temperature value around \([0.05, 0.1]\) yields good performance.

**Scalability:** Many MARL algorithms which use a centralized critic such as MADDPG [16] can suffer from the problem of scalability due to increasing joint state-action space as the number of agents increases. VM3-AC can also suffer from the same issue but we can address the problem by adopting an attention mechanism as in MAAC [8]. Additionally, VM3-AC needs more variational approximation networks as the number of agents increases. As many MARL algorithms share the parameters among agents, we can share the parameters for the variational approximation networks. We expect that parameter sharing can handle the scalability of the proposed method.

### 7 CONCLUSION

In this paper, we have proposed a new approach to MI-based coordinated MARL to induce the coordination of concurrent actions under CTDE. In the proposed approach, a common correlation-inducing random variable \( z_t \) is injected into each policy network, and the MI between actions induced by this variable is expressed as a tractable form by using a variational distribution. The derived objective consists of the maximum entropy RL combined predictability enhancement (or uncertainty reduction) for other agents’ actions, which can be interpreted as correlated exploration. We evaluated the derived algorithm named VM3-AC on both continuous and discrete action tasks and the numerical results show that VM3-AC outperforms other state-of-the-art baselines, especially in multi-agent tasks requiring high-quality coordination among agents.

**Limitation** One can think sharing the common variable requires communication between agents. To handle this, we introduced two methods including sharing a Gaussian random sequence generator at the beginning of the episode and injecting the mean vector into the latent vector in the execution. Here, reference timing information on top of time step synchronization is required for the method of sharing a Gaussian random generator. This requirement of communication is one limitation of our work, but we provided an ablation study on this alternative and it was seen that the alternative performs well.
